(54) Title: CONVERSION OF A VIDEO SIGNAL FOR DRIVING A LIQUID CRYSTAL DISPLAY

## (57) Abstract

Method and apparatus for the conversion or generation of a video signal intended to be displayed on an image display with different luminance response times for rise and decay. The conversion or generation of the video signal is so that motion artefacts which are caused by the difference in luminance response times for rise and decay such as large area luminance jumps, large-area flicker and faulty temporary large-area luminance are fundamentally cancelled in the displayed image.

**Conversion of a video signal for driving**  
**a liquid crystal display**

5 The present invention relates to the display of images on image displays with different luminance rise and decay response times, such as liquid crystal displays, in particular to the display of TV pictures and/or data information on a video display system equipped with a liquid crystal display device.

10 The display of video images on display devices such as a Cathode Ray Tube (CRT) or a Liquid Crystal Display (LCD) is a known art. Image displays equipped with such CRT or LCD display devices are capable of displaying on a display screen images consisting of a number of picture elements (or pixels) which are refreshed at a  
15 refresh rate generally above 25 Hz. These images may be monochromatic, multicolour or full-colour. Common standards are in use to display the images as a succession of frames.

The light of the successive frames which are displayed on the display screen of such a CRT or LCD display device is integrated by  
20 the human eye. If the number of displayed frames per second - further called the frame rate - is sufficiently high, an illusion of the images being displayed in a continuous way, and therefore an illusion of motion, can be created.

The way images are formed on the display screen of a CRT display  
25 device is fundamentally different from the way images are formed on the display screen of a LCD display device.

On a CRT display device, the luminance of a picture element is produced by an area of a phosphor layer in the display screen when said area is hit by a writing electron beam.

30 On a LCD display device, the luminance of a picture element is determined by the light transmittance state of one or more liquid crystal elements in the display screen of the LCD display device at the location of the picture element, whereby the light itself originates from ambient light or a light source.

35 For a faithful reproduction of moving images or moving parts of an image, the luminance response of the used display device is of utmost importance.

The luminance responses and the luminance response times of display screens are known to be very different for CRT and LCD  
-40 display devices. The luminance response time, being the time needed to reach the correct luminance on the display screen in response to an immediate change in a corresponding drive signal is shorter than a frame period for a CRT display device but up to several frame

periods for a typical LCD display device according to the state of the art.

For LCD display devices, the luminance responses and luminance response times are also known to be different for a darker-to-brighter luminance transition as compared to the responses and response times for a similar brighter-to-darker luminance transition. Furthermore, the luminance responses and luminance response times are temperature dependent, drive voltage range dependent and, due to production tolerances, unequal over the LCD screen area (location dependent).

Various solutions are known for changing luminance response times with LCD display devices. They however have the aim to shorten the overall luminance response times, not to make the luminance rise and decay times equal. EP 0 487 140 discloses a method for speeding up display response times by doubling the display frame rate. The luminance rise and decay times remain different. EP 0 553 865 describes luminance flicker phenomena related to luminance response, but this flicker is not due to the difference between luminance rise and decay times, but by how image lines are written.

There exist, a number of images, further referred to as specific images, which when moved over a display screen with different luminance rise and decay times, give rise to visible and measurable artefacts in the displayed image, even when the luminance responses are shortened.

It is characterising for said specific images that they contain a number of isolated or clustered picture points, which are in high contrast to their surroundings in the image.

The artefacts are due to the difference between luminance rise and decay times, which is typical for a LCD display device. This causes the luminance decay (or rise) of a white spot at a first location to be different from the simultaneous luminance rise (or decay) of a white spot at a second location, when the white spot is moved from the first to the second location. The total luminance integrated over the screen area immediately before, during and after the movement of the white point is not constant. The integrated luminance shows a 'luminance jump'.

In practice, the artefacts will only be visible when more picture elements change luminance at the same time within the observation field of the viewer.

In practice, various different artefacts may appear dependent on various parameters such as the difference between luminance rise and decay times, the frame rate of the displayed image, the video signal levels, the speed with which the image is moved over the screen, the image content.

The visible artefacts cause the quality of the displayed image to range from being inferior to unacceptable . The known solutions of increasing the frame rate do not fundamentally solve the problems but only make them in the best case less perceptible.

5 It is the aim of this present invention to remove the said luminance jumps and all the visible artefacts resulting from said luminance jumps in a displayed image during and immediately after the movement of the image, the luminance jumps and the artefacts caused by a difference in luminance rise and decay times of the  
10 display screen on which the image is displayed.

This is obtained by a method for converting a first video signal into a second video signal, the second video signal being intended for being displayed on a display device with different luminance  
15 rise and decay times, which comprises a display screen, and which operates at a frame period. The conversion is so that the second video signal causes the luminance time response of a picture element of the image to a change of the first video signal from a first amplitude value to a second amplitude value to be substantially  
20 equal in shape and amplitude but reversed in slope compared to the luminance time response of the same or another picture element of the said image to a change of the first video signal from the said second amplitude value to the said first amplitude value. The luminance time responses can be made substantially equal to  
25 'predefined luminance time responses'. The luminance time responses can be made substantially equal in amplitude and not slower than the luminance response of the same or another picture element which would be caused by the first video signal if this was displayed without conversion. The choice of the said same or another picture  
30 element can be the said same picture element itself, a reference picture element from a selected group of picture elements (e.g. a window) to which said same picture element belongs, any picture element which can be displayed on the display screen of the display device. The chosen said same or another picture element can be that  
35 picture element of all picture elements which are aimed to be displayed of which the luminance response is the slowest. The conversion permits the compensation of the unevenness of the luminance rise and decay times over the surface of the display screen, as well as the compensation of the temperature dependency of  
40 the luminance rise and decay times.

According to a preferred embodiment, the conversion is such that the second video signal is built up in real time in consecutive steps during corresponding consecutive correction periods.

For the determination of a next step, one or more of the following parameters may be taken into account at the start of a correction period:

- 5       - the present luminance of the picture element as predicted at the instant of the previous correction period,
- the present amplitude of the first video signal,
- the physical location of the picture element on the display screen,
- the present temperature at the location of the picture element.

10       Preferably, a correction period is equal to a multiple of the frame period of the second video signal.

      Preferably, the frame rate of the second video signal is a multiple of the frame rate of the first video signal.

15       According to an embodiment of the present invention, the conversion of the first video signal into the second video signal is so that the faster luminance response of a picture element to a change of the first video signal is slowed down in order to match the luminance response in time and amplitude to the known slower luminance response of the same or another picture element for the opposite change of the first video signal.

20       According to another embodiment of the present invention, the conversion of the first video signal to the second video signal is so that the slower luminance response of a picture element to a change of the first video signal is accelerated in order to match the luminance response in time and amplitude to the known faster luminance response of the same or another picture element for the opposite change of the first video signal.

25       According to another embodiment of the present invention, the conversion of the first video signal to the second video signal is so that the second video signal causes the luminance time response of a picture element to a change of the first video signal from a first amplitude value to a second amplitude value to be substantially equal in shape and amplitude but reversed in slope compared to the luminance time response of the same or another picture element for a change of the first video signal from the said second amplitude value to the said first amplitude level, the luminance responses being equal to predefined luminance responses.

35       Furthermore, an apparatus is claimed for carrying out a method as described hereinabout.

Fig. 21 shows a video generator which is connected to an image display which contains an apparatus according to the invention;

A first example of a specific image is illustrated in Fig. 1a, Fig. 1b and Fig. 1c. An image display 1 has on its display screen 2 a specific image 3 characterised by a high noise content, the image being scrolling down at such a slow speed that the scrolling steps are individually perceptible. Fig. 1b shows an enlarged part 4 of the specific image 3, its location referred to the image being shown in Fig. 1a. Fig. 1b and Fig. 1c illustrate a downward scrolling step equal to the difference between the distance 5 of a bright image point 6 to the top border of the image before a scrolling step and the distance 7 after the scrolling step. A second example of a specific image is illustrated in Fig. 2 and shows a window 8 with text inside, which is moved over a display screen 2 from a location 9 to a location 10. Depending on the luminance rise and decay responses of the display device and on the scrolling or movement speed, artefacts are seen as a large-area luminance flash, large-area luminance flicker, a temporary faulty large-area luminance.

Fig. 3a, Fig. 3b and Fig. 3c illustrate the movement on a display screen of a white point 11 with the dimension of a picture element from a first position 12 (Fig. 3a) to a second position 13 (Fig.

3c). Only a small part 14 of the display screen enclosing the two locations 12 and 13 is shown in an enlarged way.

When the white point changes instantly from the said first position 12 to the said second position 13, the following happens.

5     On a display screen of which the luminance response is immediate, the white point will at the same instant fully disappear at the first location 12 and fully reappear at the second location 13; the luminance integrated over the screen area 14 at time instances before, during and after the move of the white point will be equal  
10    to the luminance corresponding to one white point.

On a display screen with a luminance rise time different compared to the luminance decay time as it is typical for an LCD display device, the luminance decay (or rise) of the white spot at the first location 12 will be different from the simultaneous luminance rise  
15   (or decay) of the white spot at the same instant at the second location 13; the total luminance integrated over the screen area 14 is not equal immediately before, during and after the movement of the white point.

In Fig. 4 is shown the luminance before, during and after the  
20   movement of the white point 11 at a time instant  $T_0$  from a first location 12 to a second location 13 on a display screen of which the luminance rise time is shorter than the luminance decay time. The horizontal axis 15 is a time scale and the vertical axis 16 is a luminance scale. Graph 17 shows the luminance of the picture element  
25   at the first location 12, graph 18 shows the luminance of the screen picture element at the second location 13, and graph 19 shows the integrated luminance over the screen area 14.

In Fig. 5 is shown the luminance before, during and after the  
30   move of the white point 11 at a time instant  $T_0$  from a first position 12 to a second position 13 on a display screen of which the luminance rise time is longer than the luminance decay time. Graph 20 shows the luminance of the picture element at the first location 12, graph 21 shows luminance of the picture element at the second location 13, and graph 22 shows the integrated luminance over the  
35   screen area 14.

Fig. 4 and Fig. 5 show that when the white point 11 moves from the first position 12 to the second position 13, there is a short luminance jump, upwards or downwards depending on how the rise and decay times of the display screen relate to each other. Within a  
40   same time period, the luminance of the picture element at the second location 13 is changed differently compared the luminance of the picture element at the first location 12, the difference determining the amplitude of the luminance jump. This luminance jump is at the origin of the artefacts mentioned above and further explained below.

If more white points are moved at the same instant and within the same small area of the display screen, a luminance jump will occur as well but its amplitude depends on how the white points are distributed within the same area.

5 Fig. 6a, Fig. 6b and Fig. 6c illustrate how two white points laying side-by-side move in the same horizontal direction over a distance of one picture element. In Fig. 6b is shown that one picture element does not change luminance, while two other picture elements change luminance. Compared to the move of one white point  
10 as described above, the amplitude of the luminance jump within the area 14 is equal, however the relative luminance jump being the absolute luminance jump related to the total luminance of the moving points is smaller.

Fig. 7a, Fig. 7b and Fig. 7c illustrate how three white points  
15 laying side-by-side move in the same horizontal direction over a distance of one picture element. In Fig. 7b is shown that two picture elements do not change luminance, while two other picture elements change luminance. Compared to the move of one white point as described above, the amplitude of the luminance jump within the  
20 area 14 is equal. Compared to the move of two white points as described above, the amplitude of the luminance jump within the area 14 is equal, however the relative luminance jump being the absolute luminance jump related to the total luminance of the moving points is smaller.

25 Fig. 8a, Fig. 8b and Fig. 8c illustrate how two white points above each other move in the same vertical direction over a distance of one picture element. In Fig. 8 is shown that four picture elements do change luminance at the same time. Compared to the move of one white point, the luminance jump is doubled, but the relative  
30 luminance jump is the same.

Different combinations of white points moving at the same time in a same direction from one first location to a second location within an area of the image screen will give different absolute and relative luminance jumps within that said area. In Fig. 9a, Fig. 9b  
35 and Fig. 9c is illustrated a movement of a larger combination or cluster of white points from one location to a more right-down location.

Fig. 10 illustrates a white point 11 moving during a time interval T0-T3 of 3 frame periods from location 23 to location 26  
40 over locations 24 and 25, within a screen area 14. Fig. 11 shows the luminance graph 27 in function of time, integrated over the area 14. A temporary lower luminance 28 occurs during the move of the white point. The luminance is temporarily faulty. This artefact is related to the image jump and further mentioned as a 'temporary faulty  
45 luminance'.

The 'luminance jump' and 'temporary faulty luminance' artefacts were explained hereabove for simple moving images composed of one or more white points. These artefacts however occur more or less visible and/or measurable with any image moved on a display screen of an image device with different luminance rise and decay times. When an above mentioned specific image, for example the image illustrated by means of Fig. 1a, is moved over the screen whereby its content remains unchanged, depending on the speed of the movement, artefacts ranging from a luminance jump (or a brighter or darker luminance flash), over a large-area flicker to a large-area faulty luminance may occur. The artefacts occur only in the images or in parts of the image which are moved.

In Fig. 12 is shown a prior art connection of a video generator 29 to an image display 1.

An embodiment of the present invention is explained by means of block diagram Fig. 13 and figures of waveforms. It is an apparatus in which a first video signal is converted into a second video signal.

Fig. 13 shows a block diagram of an apparatus 32 according to the present invention. The input is a first video signal 33, and the output is a second video signal 34 which is a conversion of the first video signal 33. The apparatus 32 comprises several functional blocks, being an optional inverse gamma correction 35, a subtractor 36, a first adder 37, a second adder 38, a processing block 39, a one-frame memory FM, and an optional gamma-correction 40. The said functional blocks are interconnected through several interconnections for the interchange of values between the functional blocks. These values may correspond to luminances, or to gamma-corrected video signals, or to video signals without gamma-correction, or to a combination of one or more of these, depending on where the apparatus 32 is located in a video chain between a video generator and a display device. For the description of the apparatus 32, it is assumed that the values are linearly related to luminances on the display screen and that the first and second video signals are not gamma-corrected. It will however be easy to extend the apparatus for gamma-corrected video signals by the addition of an inverse gamma-correction 35 at the input side, and a gamma-correction 40 at the output side, or by integrating gamma-awareness into the apparatus 32.

The processing block 39 has an optional input for values TL, these values being related to the present status of a picture element of the display screen such as temperature, location of the picture element being processed, differences in display behaviour between production batches, ageing of the display, intended to be used for compensations in the conversion of the first video signal

into the second video signal. These values may come from a sensor in the display device, or be user-configurable through an on-screen display or an external data entry device.

For the explanation of the operation of the apparatus 32, a first video signal IN1 as shown on Fig. 14a is chosen. This chosen first video signal corresponds to a white picture element on a black background, the white picture element appearing at time T0 and disappearing at time T10. In Fig. 14a, the horizontal axis is a linear time scale with divisions TF1 corresponding to frame periods of the first video signal, and the vertical axis is a linear voltage scale. The first video signal amplitude changes at T0 from I0 to I1, and at T10 from I1 to I0.

Fig 14b shows the waveform of the RMS drive voltage applied inside a typical LCD display device to the one or more liquid crystal image cell(s) of the display screen of LCD display device which are driven to display the white point of the first video signal IN1 and this according to prior art.

Fig. 15a shows a number of luminance time responses of a picture element on a display screen of an LCD display device of which the luminance rise time is shorter than the luminance decay time. The horizontal axis is a linear time scale, and the vertical axis 41 is a linear luminance scale. The luminance responses in Fig. 15a correspond to one unique LCD display device; the response is dependent on the display device, the location of the picture element on the display screen, on the temperature.

Graph 42 on Fig. 15a shows the prior art luminance response to the first video signal IN1 at the location of the displayed picture element. As shown, the luminance rises from time instant T0 for a duration of several frame periods from L0 to L1, and decays from time instant T10 for a duration of several frame periods. The luminance rise time is shorter than the luminance decay time.

Graph 43 shows the prior art luminance response of the same picture element to a first video signal which is reversed in amplitude compared to video signal IN1 and which is further called -IN1. Luminance rise and decay times are as with Graph 42.

Video signals IN1 and -IN1 do not occur at the same instant for driving the same picture element, but may both be present at the input within a time interval shorter than an input frame period when e.g. a white picture element moves from one location to another within the image.

According to the present invention, the luminance rise and decay times are made equal, obtained by slowing down the faster response to match with the slower response, or accelerate the slower response to match with the faster response, or make the faster and the slower response equal to a predefined luminance response, the three methods

being possible with the here described embodiment. Accelerating the slower response will however not always be useable in practice because higher drive voltages will be needed and saturation may occur in the image display.

5     The solution is only fully explained for making the faster response slower. Making the slower response faster, or making the faster response and the slower response equal to predefined responses, can easily be implemented by the skilled person.

10    In accordance with the present invention, graph 42 in Fig. 15a is slowed down to graph 44 during the time interval of rising luminance and matches as close as possible to graph 45 being the reverse of graph 43. During the interval of decaying luminance (from T10 on), the response should not be modified and remain as graph 42.

15    Fig. 16 is an enlarged version of a part of Fig. 15a, namely between time instances T0 and T3. To the first vertical axis 41 is added a second vertical axis 46 in order to show the relation between the second video signal and the luminance of the image on the display screen.

20    The method for converting the first video signal into the second video is further explained referring to the block diagram Fig. 13.

25    The conversion is such that the second video signal is built up in real time in consecutive steps during corresponding consecutive correction periods TC. A correction period (TC) is by preference equal to the frame period of the displayed image. A correction period may be different from the frame period (TF1) of the first video signal.

30    From the present value of the first video signal 33 is subtracted in the subtractor 36 a value FR which corresponds to the present luminance as it was predicted one correction period before. The result is a value  $\Delta$ . The value  $\Delta$  determines how the luminance will have to change during the next correction period. Luminance should increase or rise when  $\Delta$  is positive, decrease or decay when  $\Delta$  is negative, and remain equal when  $\Delta$  is zero. The value  $\Delta$  is applied to a first input of the processing block 39. At a second input is applied the predicted present luminance FR. With as input values  $\Delta$  and FR and if present the input of one or more temperature values TL related to the connected display screen, are determined two output values,  $\Delta C$  and  $\Delta R$ . How these values  $\Delta C$  and  $\Delta R$  can be determined is explained further.  $\Delta C$  is a correction value to be added to the  
40    predicted present luminance FR in order to reach a chosen luminance (to match to a chosen response) at the end of the next correction period.  $\Delta R$  is the value with which the luminance will have changed

after the next correction period when  $\Delta C$  is added to the predicted present luminance FR taking into account the parameters of the display screen (of which some are screen-location, voltage and temperature dependent).

5       The said value  $\Delta C$  is added in the first adder block 37 to the predicted present luminance FR. Said predicted present luminance FR was predicted at the beginning of the previous correction period and has been delayed over one correction period in a one-correction-period memory FM. The output of the first adder 37 is a value which  
10 is the second video signal 34 without optional gamma-correction.

      The value  $\Delta R$  is added in the second adder block 38 to the value of the predicted present luminance FR. The output is the predicted present luminance for a next correction period.

      Although a correction to the second video signal takes several  
15 correction periods, a memory FM of only one correction period (or only one second video signal frame period) is needed. Per correction period is determined a new correction value based on the present luminance which was calculated at the start of the previous correction period and stored during one correction period.

20       The above described apparatus 32 contains all the above mentioned functional blocks and connections to change a luminance response in consecutive steps by converting the first video signal 33 to the second video signal 34. It is however not always needed to change the luminance response, namely when the luminance response already  
25 follows the slowest response with the first video signal, the apparatus can work transparently. This can be realised in the processing block 39.

      For further explanation is referred now to Fig. 16 in which is shown how the luminance response is built up during three  
30 consecutive correction periods from the time instances T0 to T3.

      From T0 to T1, without correction, the luminance rise would follow graph 42 and increase from LF to LA1. According to the invention, the luminance response should however follow graph 45 and increase from LF to LB1. The shape of the rising luminance slope is  
35 however not exactly identical to the opposite of the shape of the decaying luminance slope, and so it is difficult to match the rising luminance to the graph 45 and at the same time reach luminance LB1 at time instant T1. More important is however that the integrated luminance over the correction period from T0 to T1 is correct.  
40 Therefor, the luminance should raise so that the integrated luminance is the same as it would be if graph 45 was followed and LB1 reached at T1. This is so when the luminance follows the exponential graph 47, whereby the luminance is LD1 at T1. The

corrected luminance response is marked as 44 on Fig. 16 (and Fig. 15a). Referring to Fig. 13 and its explanation,  $\Delta C$  should have an appropriate value to correct the second video signal so that the luminance increases to  $LC1$  over a number of correction periods;  $LD1$  is the predicted present luminance  $FR$  at the end of the correction period  $T0-T1$ .

At  $T1$ , a following correction period  $T1-T2$  starts. The luminance should continue to follow as closely as possible graph 45 and at the same time, the integrated luminance over  $T1-T2$  should be equal as if the luminance response would follow graph 45. Therefor, the luminance should rise (graph 48) to the luminance  $LC2$  and rise from  $LD1$  to  $LD2$  within the correction period  $T1-T2$ .  $LD2$  is the predicted present luminance after the correction  $T1-T2$ . If the video signal would not have been corrected, a luminance  $LA2$  would have been reached at  $T2$ .

On the vertical axis 46 in Fig. 16 are set out values with reference to Fig. 13 and its explanation. The first video signal amplitude value goes from  $INF$  to  $INT$  at  $T0$ . At  $T1$ , the difference between the value of the first video signal and the predicted present luminance  $FR$  predicted at  $T0$ , is  $\Delta 1 = INT - FR1$ . The output of the processing block is  $\Delta C1$  and is added to  $FR1$  to be the new second video signal value. The predicted rise of luminance after the correction period  $T1-T2$  is  $\Delta R1$ , and the predicted present luminance at  $T2$  is  $FR1 + \Delta R1 = FR2$ . From  $T2$  on, the luminance response is built up in the same way as described here before up to a luminance  $LT$ . On Fig. 15a is shown, that from  $T10$ , the luminance response follows the slower luminance decaying response and no correction is carried out, the apparatus 32 working transparently.

Fig 15b shows the waveform of the RMS drive voltage with reference to Fig. 14b, but now in response to the second video signal.

In Fig. 15c is shown the second video signal, being the converted first video signal shown in Fig. 14a.

In Fig. 17a, Fig. 17b and Fig. 17c are shown similar waveforms compared to Fig. 15a, Fig. 15b and Fig. 15c, however for a display device of which the luminance rise time is longer than the luminance decay time. The luminance decay is now made slower from  $T10$ .

In the processing block 39, the output values  $\Delta C$  and  $\Delta R$  are determined in function of the input values  $\Delta$  and  $FR$  and optional temperature values and location values. The following C-language function is hereby used.

```

-----
void calc_deltas(int delta_in, int from, int *delta_out, int
*delta_res)
{
5   float dout, dres;

   if (delta_in > 0) /* positive slope */
   {
       /* no drive correction needed */
10      dout = delta_in;
   }
   else /* negative slope */
   {
       /* correction value */
15      dout = (float)delta_in *
              ( (FRAME_PERIOD - tau_rising * (1 - exp(-
FRAME_PERIOD/tau_rising)))
                / (FRAME_PERIOD - tau_decaying * (1 - exp(-
FRAME_PERIOD/tau_decaying)))
20      )
          * temp_function(temperature, DECAYING)
          * location_function(screen_x,screen_y);
   }

25   /*
    * Predict pixel response. To be used in next frame iteration.
    * Always predict the slowest edge, since that is what we want
to
    * make the fastest one do as well .
30   */
    dres = (float)delta_in
          * (1 - exp(-FRAME_PERIOD/tau_rising))
          * temp_function(temperature, RISING)
          * location_function(screen_x,screen_y);
35
    *delta_out = (int)rint(dout);
    *delta_res = (int)rint(dres);
}
-----

```

40

In the above shown C-language function, corrections are determined every 1/60 second (frame rate 60 Hz). It is written for the display of an image on a display device of which the luminance rise time is longer than the luminance decay time. Values

45 "delta\_out" (being  $\Delta C$ ) and "dres" (being  $\Delta R$ ) are calculated from "delta\_in" (being  $\Delta$ ) and "from" (being FR). When "delta\_in" is positive, the luminance should rise (called positive slope) and no correction is to be made. The calculation of dout (or  $\Delta C$ ) is based on the following equation wherein T is the correction period :

$$\Delta C = \Delta \cdot \frac{T - \tau_r \cdot \left( 1 - e^{-\frac{T}{\tau_r}} \right)}{T - \tau_r \cdot \left( 1 - e^{-\frac{T}{\tau_r}} \right)}$$

The calculation of "dres" ( $\Delta R$ ) is based on the following equation :

$$\Delta R = \Delta \cdot \left( 1 - e^{-\frac{T}{\tau_r}} \right)$$

5  $\tau_r$  (or tau\_rising) and  $\tau_d$  (or tau\_decaying) are time constants of exponential functions corresponding to luminance time responses.

The C-program function includes a correction in function of temperature (temp\_function) and location (location\_function).

10 The processing block 39 may be implemented in different ways. It may be a pre-calculated look-up table with  $\Delta$  and FR as input values, and  $\Delta C$  and  $\Delta R$  as output values which before being output are sent through multipliers for temperature and location dependent corrections.

15 It may be a hardware implementation of the C-program function shown above.

It may consist of a look-up table and a microprocessor to update the values in the look-up table in function of temperature.

Fig. 18, Fig. 19, Fig. 20 and Fig. 21 show other possible embodiments or applications of the present invention. Fig. 18 shows  
20 a stand-alone apparatus 49 which converts according to the present invention a first video signal 33 into a second video signal 34, having an optional input 50 for values (TL) related to a display screen and having an optional temperature sensor 51 for measuring a temperature of a display screen. Fig. 19 shows an apparatus  
25 according to the invention 52 which is connected between a video generator 29 and an image display 1. Fig. 20 shows an apparatus according to the present invention 52 built-in inside a signal generator 29 which is connected to an image display 1. Fig. 21 shows an apparatus according to the present invention 52 built-in inside  
30 an image display which is connected to a video generator 29.

It is also a possible application of the present invention that a video signal is generated or converted inside a signal generator so that the luminance time responses of a picture element of an image, displayed on a display device with different luminance rise and decay times, are equal for an amplitude change of the video signal and for the opposite amplitude change of the video signal.

**Claims**

- 1.-A method for the conversion of a first video signal into a second video signal, the second video signal being intended for being displayed on a display device with different luminance rise and decay times, the display device comprising a display screen, and operating at a frame period, characterised in that the conversion is so that the second video signal causes the luminance time response of a picture element of the image to a change of the first video signal from a first amplitude value to a second amplitude value to be substantially equal in shape and amplitude but reversed in slope compared to the luminance time response of the same or another picture element of the said image to a change of the first video signal from the said second amplitude value to the said first amplitude value.
- 2.-A method according to claim 1, whereby the said luminance time responses are substantially equal in amplitude and not slower than the luminance response of the same or another picture element caused by the first video signal displayed without conversion.
- 3.-A method according to claim 1, whereby the said luminance time responses are substantially equal to predefined luminance time responses.
- 4.-A method according to any of the preceding claims, whereby the conversion of the first video signal into the second video signal is so that the second video signal is built up in consecutive steps during corresponding consecutive correction periods.
- 5.- A method according to claim 4, whereby at the start of a correction period, for the determination of the next step, one or more of the following parameters are taken into account :
- the present luminance of the picture element as predicted at the instant of the previous correction period,
  - the present amplitude of the first video signal,
  - the physical location of the picture element on the display screen,
  - the present temperature at the location of the picture element.
- 6.- A method according to any of claims 4 or 5, whereby a correction period is equal to a multiple of the frame period of the first video signal.
- 7.- A method according to any one of the preceding claims, whereby the frame rate of the second video signal is different from the frame rate of the first video signal.
- 8.- A method according to one of the claims 1, 2, 4, 5, 6 and 7, whereby the conversion of the first video signal into the second video signal is so that the luminance response of a picture

element of the display screen to a change of the first video signal is slowed down in order to match the luminance response in time and amplitude to the known slower luminance response of the same or another picture element for the opposite change of the first video signal.

9.- A method according to one of the claims 1, 2, 4, 5, 6 and 7, whereby the conversion of the first video signal to the second video signal is so that the luminance response of a picture element of the display screen to a change of the first video signal is accelerated in order to match the luminance response in time and amplitude to the known faster luminance response of the same or another picture element for the opposite change of the first video signal.

10.- An apparatus (32) for converting a first video signal (33) into a second video signal (34), characterised in that it comprises :

- a subtractor (36) for subtracting from the first video signal (33) a predicted present luminance,
- a processing block (39), having as input the output of the subtractor and the predicted present luminance, and as output a first and a second correction value,
- a first adder (37) for adding the first correction value of the processing block (39) and the predicted present luminance, thus forming the second video signal (34),
- a second adder for adding the second correction value and the predicted present luminance, thus forming the next predicted present luminance,
- a one-frame memory, for delaying the next predicted present luminance, thus forming the predicted present luminance for a next correction period.
